PURPOSE. Reduction in inner retinal oxygen delivery (DO₂) can cause retinal hypoxia and impair inner retinal oxygen metabolism (MO₂), leading to vision loss. The purpose of the current study was to establish measurements of DO₂ and MO₂ in healthy subjects and test the hypothesis that DO₂ and MO₂ are reduced in sickle cell retinopathy (SCR) subjects.

METHODS. Dual wavelength retinal oximetry and Doppler optical coherence tomography were performed in 12 healthy control and 12 SCR subjects. Images were analyzed to measure retinal arterial and venous oxygen content (O₂A and O₂V), venous diameter (D V), and total retinal blood flow (TRBF). Retinal arteriovenous oxygen content difference (O₂AV), DO₂, MO₂, and oxygen extraction fraction (OEF) were calculated according to the following equations: O₂AV = O₂A − O₂V; DO₂ = TRBF * O₂AV; MO₂ = TRBF * O₂AV; OEF = MO₂/DO₂.

RESULTS. Retinal DV and TRBF were higher in the SCR group as compared to the control group, whereas, O₂A, O₂V and O₂AV were lower in SCR group as compared to the control group. MO₂ and DO₂ were linearly related, such that higher MO₂ was associated with higher DO₂. There was an inverse relationship between TRBF and OEF such that lower TRBF was associated with higher OEF.

CONCLUSIONS. Increased blood flow compensated for decreased oxygen content, thereby maintaining DO₂, MO₂, and OEF at predominately lower stages of SCR. Quantitative assessment of these parameters has the potential to advance knowledge and improve diagnostic evaluation of retinal ischemic conditions.

Keywords: oxygen metabolism, oxygen extraction fraction, blood flow, sickle cell retinopathy

The retinal tissue requires oxygen and nutrients to maintain normal function for visual processing. Reduction in inner retinal oxygen delivery (DO₂) can cause retinal hypoxia and impair inner retinal oxygen metabolism (MO₂), leading to vision loss. Therefore, it is imperative to develop methods for quantitative assessment of these key parameters under normal and retinal ischemic conditions. To this end, methods have been developed for assessment of MO₂ in humans by combining spectrophotometry to measure retinal vascular oxygen saturation (SO₂) with Doppler optical coherence tomography (OCT) to measure total retinal blood flow (TRBF). Various approaches to quantify TRBF using Doppler OCT have been described previously. In order to integrate flow in a blood vessel sectioned on an OCT B-scan, the angle between the OCT beam and the direction of blood flow was obtained using double circular scans, resampled from volume scans, or created by dual-beam OCT. Alternatively, to minimize the error associated with angle determination, a dual-angle Doppler OCT, dual-beam OCT with a known angular offset between beams was used. Furthermore, to obviate the need for angle calculation, an en face Doppler OCT approach employs high-speed three-dimensional volumetric OCT and integrates flow across an en face section of the blood vessel. However, to measure the high axial blood velocity in the central retinal vein or artery, high-speed (200 kHz or higher) OCT systems were necessary. In order to apply the en face method on slower Doppler OCT systems (70–100 kHz), measurements were obtained on vessel branches with lower blood velocity using tilted planes or multiple en face planes.

To date, calculated measurements of DO₂ have not been reported in humans. Since DO₂ is the product of TRBF and arterial oxygen content, TRBF alone provides only partial information about oxygen delivery to the retina. Similarly, MO₂ is the product of TRBF and arteriovenous O₂ difference, thus measuring either SO₂ or TRBF individually would likely lead to incorrect conclusions with regard to MO₂. Alternatively, MO₂ can be expressed as the product of DO₂ and the inner retinal oxygen extraction fraction (OEF). OEF quantifies how much of the oxygen available from the retinal vasculature is extracted by the retinal tissue for metabolism. Under physiologic or pathologic challenges, compensatory changes in DO₂ and OEF respond in order to maintain MO₂. Conversely, alterations in MO₂ can play a role in regulating DO₂. In healthy subjects, MO₂ was measured under normoxia and hyperoxia. Furthermore, MO₂ was shown to be reduced in subjects with diabetic retinopathy, however, MO₂ has not been evaluated in sickle cell retinopathy (SCR), in which vision threatening retinal capillary occlusions, nonperfusion, ische-
The raw spectral data with 500 A-lines/B-scan, and the three-dimensional volumetric consecutive volume scans. Each volume contained 80 B-scans retinal vein were acquired. Each image consisted of five images covering a 2×3 area on the en face plane (Fig. 1). Veins were distinguished from arteries by the sign of the Doppler shift and flow calculation.

The purpose of the current study was to establish measurements of TRBF and retinal vascular SO2. TRBF was computed as the sum of flow in all individual detected retinal veins from different en face planes. To reduce measurement variability, the TRBF measurements from all volumes were averaged. A grader excluded volumes in which motion artifacts interfered with vein identification or flow calculation. Data were included from an average of nine volumes, range between 3 and 15.

For vascular SO2 measurements, dual wavelength (570 and 606 nm) retinal oximetry was performed using our custom-built slit lamp biomicroscope and previously published method. At each imaging wavelength, nine retinal images were acquired in a 5×5-mm area centered on the optic disk. An example of a retinal image acquired at 570 nm in a healthy control subject is shown in Figure 1. Retinal images were analyzed using a custom software written in MATLAB (Mathworks, Natick, MA, USA) to measure vessel diameter and SO2 in all retinal vessels within a circumpapillary region of interest extending between one and two disk radii from the perimeter of the optic disk (Fig. 1). Vessel diameter was determined by calculating the full width at half maximum of intensity profiles perpendicular to the vessel centerlines. Retinal arterial and venous diameter (D A and D V respectively) and SO2 (SO2A and SO2V respectively) were determined for each blood vessel by averaging multiple values along the vessel segment. Blood oxygen content of retinal arteries and veins (O2A and O2V) were determined by the following relation: O2 = O2max * Hgb * SO2, where O2max is the oxygen-binding capacity of hemoglobin and Hgb is the hemoglobin concentration calculated from the measured HCT values. Mean values of Dv, O2A, and O2V were determined per eye by averaging measurements in all retinal arteries and veins.

Retinal arteriovenous oxygen content difference (O2AV) was calculated as O2A – O2V. DO2, MO2, and OEF were calculated according to the following equations: DO2 = TRBF × O2A; MO2 = TRBF × O2AV; OEF = MO2/DO2.

### Statistical Analysis

Compiled retinal oxygen metrics (Dv, TRBF, O2A, O2V, O2AV, DO2, MO2, and OEF), demographic, and systemic physiologic data were compared between groups using unpaired t-tests. Linear regression analysis was performed to determine the significance of associations between metrics. Statistical analyses were performed using statistical software (SSPS Statistics, version 24; IBM Armonk, New York, USA). Statistical tests were two-sided and significance was accepted at P ≤ 0.05.

### RESULTS

Age of control and SCR subjects was 41 ± 15 years and 38 ± 14 years (mean ± standard deviation), respectively (P = 0.62). MAP of control and SCR subjects was 95 ± 10 mm Hg and 86 ± 12 mm Hg, respectively (P = 0.06). HCT of SCR subjects (33% ± 7%) was lower than that of control subjects (45% ± 6%) (P < 0.001).

The Table lists retinal oxygen metrics in control and SCR groups. Retinal Dv and TRBF were higher in the SCR group as compared to the control group. O2A, O2V, and O2AV were lower in the SCR group as compared to the control group. DO2, MO2, and OEF were not significantly different between control and SCR groups. As shown in Figure 2, there was a linear relationship between MO2 and DO2, such that higher MO2 was associated with higher DO2 (r = 0.67; P < 0.001; N = 24). As shown in Figure 3, lower TRBF was associated with higher OEF, with a significant linear fit to the data (r = -0.55; P = 0.005; N = 24).
TRBF was consistent with previously published values of DO. Moreover, OEF values derived from direct fit line to the data is shown.

MO2 is indicative of oxygen consumption rate. However, under supplied in healthy and SCR subjects was likely similar, thus retinal circulation. In the current study, the amount of tissue consumption rate and the amount of tissue supplied by the previous OEF values obtained by oximetry alone.18

normal physiological condition, which is consistent with a regulatory mechanism to compensate for the reduced O2.

The observed vasodilation and increased TRBF in SCR suggests a regulatory mechanism to compensate for the reduced O2.

As expected, blood O2 contents of retinal arteries and veins were reduced in SCR subjects due to the lower systemic HCT. The observed vasodilation and increased TRBF in SCR suggests a regulatory mechanism to compensate for the reduced O2.

In the current study, SO2 was not corrected for oxygen loss across the vessel walls and not weighted by blood flow in each vessel. Furthermore, for calculation of the blood O2 content, the low level of fraction of dissolved oxygen was not included. Nevertheless, the values of arterial and venous O2 contents obtained in control subjects (0.19 and 0.13 mL O2/mL) are similar to previously reported corrected values (0.181 and 0.128 mL O2/mL).20 The oxygen-hemoglobin dissociation curves may differ between healthy and SCR subjects, although a previous study showed the difference was small at high SO2 (>92%) but shifted to the right at lower levels.47 Finally, hemoglobin absorption spectra may not be the same in healthy and SCR subjects. Differences in healthy and sickle cell hemoglobin absorption spectra have been reported based on blood samples,48,49 although measurements under physiological conditions are not readily available. In the current study, adjustments were not made for any potential differences in hemoglobin absorption spectra.

DO2 was not found to be impaired in predominately lower stages of SCR. This finding is attributed to the increased TRBF, which adequately compensated for the decreased O2A. Similarly, MO2 was maintained due to the countereffects of increased TRBF and reduced O2AV. A reduction in MO2 was expected in SCR due to peripheral arteriolar occlusions and arteriolar-venular anastomoses (shunting). The finding of unchanged MO2 suggests a higher metabolic rate per unit volume in the central retina than in the thinner peripheral retina and potentially a limited contribution of shunting in peripheral retina to altering MO2.

A linear relationship between MO2 and DO2 was established based on compiled data from all subjects. This finding indicates the rate at which oxygen is delivered by the inner retinal circulation is highly correlated with the oxygen metabolic rate. Furthermore, TRBF and OEF were shown to be inversely related, similar to findings in the brain.50 This result demonstrates the presence of a compensatory increase in OEF under conditions of decreased TRBF in order to maintain

MO2. Nevertheless, the maximum value for OEF was 0.48, which indicates OEF augmentation to supply oxygen in these SCR subjects.

Overall, our method will allow investigation of the relationships among retinal blood flow, vascular oxygen levels, and oxygen consumption under physiologically challenged and pathologic conditions. Quantitative assessment of retinal MO2, DO2, and OEF has the potential to advance knowledge of oxygen dynamics and serve as new biomarkers for disease diagnosis, progression, and treatment monitoring.
